

RELIGION AND REPRODUCTIVE BEHAVIOR IN SUB-SAHARAN AFRICA

Charles F. Westoff and Kristin Bietsch
Office of Population Research, Princeton University

Abstract

With growing public interest in Muslim and Christian relations in sub-Saharan Africa, this paper explores differences in fertility across countries by religion in countries with a sizeable population of Muslims and non-Muslims. Using Demographic and Health Survey data from 29 countries, we calculate various measures of fertility and family planning by country and religion, as well as analyze the association of religion with fertility, age at marriage, limiting desires, and contraceptive use, controlling for other socioeconomic variables. We begin our analysis by looking at the three largest religious groups in sub-Saharan Africa: Muslims, Catholics, and other Christians, and find that in most countries included, Catholic and other Christian women do not differ greatly in fertility related characteristics. However, Muslim women have higher fertility and fertility-related characteristics than non-Muslims in almost all countries.

Introduction

Research on the effects of religion on reproductive behavior has had a long history in the social sciences. Most of that research has concentrated on developed countries though in recent years, the focus has included developing countries (Jones, 2006; Morgan et al., 2002; Roudi-Fahimi, 2004; Boonstra, 2001; Akafuah, 2008; Dharmalingam, 2004; Knodel et al., 1999; Karim, 1997; Immerman, Ronald, 2003, and others). Most recently, sub-Saharan Africa has become an object of attention (Heaton, 2011; Johnson-Hanks, 2006; Kahle, 2013) The most relevant publication in the group for this research is Tim Heaton's article in 2010: "Does Religion Influence Fertility in Developing Countries" based on data for 30 countries including 17 from sub-Saharan Africa. His study documents little difference in fertility between Catholics and Protestants in that part of the world but substantially higher fertility among Muslims. His analysis concludes that the level of development and various social characteristics do not fully account for the Muslim factor in fertility. As will be seen in the following analysis, similar findings remain for more recent and more extensive data.

Population Composition

The composition of religions in the sub-Saharan African countries included in this report is summarized in Table 1. In many of the countries of West and Central Africa, Muslims are the largest subgroup; they comprise almost the entire populations of Mali, Niger and Senegal. In general, the remaining two large populations are Catholics and a variety of other Christian denominations grouped in this paper as Other Christians.

In eastern and southern Africa, women classified as Other Christians predominate with Catholics next. Muslims are a distinct minority in this region not exceeding 30 percent and typically falling below 10 percent. In Ethiopia, 47 percent identify as Orthodox.

Sources of Data

The 30 countries in Table 1 comprise those in sub-Saharan Africa with Demographic and Health Surveys conducted in the past ten years (from 2004). The religious identification is based on a single simple question “What is your religion?” The various categories were pre-coded in the interview questionnaire based on local knowledge in each country.

No other information on the subject was obtained. It is particularly unfortunate that there is no information on religiousness which would be an important component of the general topic. The available data on religion are obviously very limited. Our groupings of religion, particularly in the Other Christian category, are crude in not differentiating various denominations but such a grouping is necessary to permit inter-country comparisons.

Fertility

In Figures 1a and 1b, Total Fertility Rates (TFR) are shown for the three major religion categories in two geographic regions of sub-Saharan Africa. The calculation of the TFR requires large samples of women since it depends on reliable denominators of women in each of the seven five-year age categories, so that only Catholics, Other Christians and Muslims can be used. There is very little difference in West and Central Africa in the TFRs (Figure 1a) for Catholics and Other Christians while the Muslim fertility rates are typically though not universally higher.

In Eastern and Southern Africa countries (Figure 1b), the fertility rates of Catholics and Other Christians are also close and Muslim fertility higher except in Tanzania¹ and Uganda.

The fertility estimates in Table 2 are different from the TFRs in that they are based on currently married rather than on all women and are simple averages of the number of births in the past five years uncontrolled for age. This fertility measure does not require the larger samples needed for the TFR and therefore can include some other religions as well as the three major groups. Estimates of fertility for women who say they have no religion tend to be on the high side which is quite the opposite pattern than observed in the more developed countries. There is no obvious explanation for this though these women are less educated than women with specific religious affiliations. They are also based typically on small numbers of women.

¹ The estimates for Tanzania are based on a 2004 survey rather than the more recent 2010 survey when the question on religion was not included.

Considering the similarity of Catholic and Other Christian fertility, the generally higher fertility of Muslims, and the small number of members of other religions, the main focus of the following analyses is confined to Muslim and non-Muslim comparisons. The difference in the TFR between these two groups is summarized in Figure 2 for countries with some Muslim populations. Countries with small numbers of Muslims – Congo, Brazzaville, Congo Democratic Republic, Burundi, Madagascar, Rwanda, Zambia and Zimbabwe – are excluded from further analyses. The higher fertility for Muslims is the predominant pattern but there are several exceptions. In Chad the reverse is seen but this picture is ten years old². A similar difference is found in Tanzania in 2004. In Mali in 2012-13, the TFR for Muslims (92 percent of the population) was 6.5, lower than that for non-Muslims at 7.2³.

Recent trends in the TFR for Muslims and non-Muslims are shown in Figure 3. The most common pattern is for the rates for both populations to be moving, more or less, in the same direction. There are exceptions to this, however, in Chad, Ghana and Malawi where Muslim fertility seems to be rising in contrast to the rates for non-Muslims. In Niger and Senegal, where Muslims comprise almost the entire populations, the trends are in opposite directions with a uniform decline in Senegal and a recent increase in Niger to a TFR of 7.6 from 7.1 five years earlier. In Tanzania, Muslim fertility has been the lower of the two and declining.

Research on the association of religion with reproductive behavior typically considers both formal belief systems as well as differences in the social and economic composition of the members of various religions (Voas, 2007). Some religions may carry particular views, for example on the practice of contraception and abortion, and on marriage and the family. In the present study, the comparisons of Muslims and non-Muslims is so limiting that the focus will be on the connections with different covariates of this dichotomy such as education, wealth, child mortality, and polygyny. (Regenerus and Smith, 2005; Watkins and Ina Warriner, 2003). There is no belief system in Islam that forbids contraception (Boonstra, 2001; Karim, 1997; Weeks, 1988; Roudi-Fahmi, 2004) though some local religious leaders may believe otherwise, while the non-Muslim category is so broad as to preclude singling out specific denominations.

Plan of Analysis

The primary objective of the following analysis is to determine whether the tendency for Muslim women in sub-Saharan Africa to have higher fertility than non-Muslims (see Figure 2) reflects differences in age at marriage, number of children desired,

² An earlier study of the differences in fertility of Muslim and non-Muslim populations of West Africa (Johnson-Hanks, 2006) showed a generally similar picture with fewer and earlier surveys. The more recent data reviewed here do not support her conclusions about the differences in fertility related to whether Muslims are a minority or a majority of the population.

³ Muslim fertility in Mali is higher than that of the Other Christian group as shown in Figure 1A but lower than the larger category of non-Muslims as indicated in Figure 2. This is because of the higher rates for Animists and women in other Traditional religions.

contraceptive use, and child mortality. We explore the socio-economic covariates of these antecedents of fertility to see whether they account for the Muslim – non-Muslim differences. We begin with nuptiality.

Nuptiality

An important component of the higher fertility of Muslims lies in the greater proportion of women currently married which is related to their early age at marriage. In the Arab world, a significant part of the decline in fertility is due to changes in nuptiality (Rashad, 2000, 2005). In the 18 countries of sub-Saharan Africa included in Table 3, every country except Tanzania in 2004 shows higher proportions of Muslims currently married. Earlier age at first marriage is characteristic for Muslims with several exceptions. The average proportion married for the 18 countries is 73 percent for Muslims and 65 percent for non-Muslims. The average age at first marriage (for ever-married women) is about one year earlier for Muslim women (17.3) than for non-Muslims (18.2). In Nigeria, the difference is four years. Polygyny is also more common for Muslims with an average of 35 percent of women in polygynous marriages compared with 24 percent for non-Muslims. According to Islamic law, a man may have more than one wife though in many countries (e.g., Turkey and Tunisia) it is forbidden by law. Moreover, the practice has declined in recent years.

Two background factors usually associated with both nuptiality and fertility are education and urban-rural residence. Their connections are explored in Table 4. In 15 of the 18 countries, the percentages of Muslim women with no schooling are higher than for non-Muslims. The three exceptions are in Mali, Tanzania and Uganda. The latter two countries have low proportions with no schooling and show lower fertility for Muslims. In Kenya, there is a large difference with 44 percent of Muslims compared with only 6 percent of non-Muslim women in this category. Muslims in Kenya are concentrated in the two least developed regions – the Northeast and the Coastal regions. In the Northeast, 97 percent of the population are Muslim and 39 percent in the Coastal region compared with only 7 percent nationally. The mean years of schooling, with the same three country exceptions, are all lower for Muslim women. Nigeria shows a particularly large difference between the two categories with an average of 9.2 years for non-Muslims and 3.2 years for Muslim women.

The differences between the two religious groups in the proportions living in cities are mixed with about half of the countries showing Muslims in more rural areas and half in more urban settings.

A multiple regression analysis with these and several other covariates of age at marriage (for ever-married women) is shown for each country in Table 5. The standardized regression coefficients showing the association of the Muslim – non-Muslim distinction with age at marriage are generally negative and significant, indicating lower ages at marriage for Muslims in the presence of four other covariates – residence, education, polygyny, and age. In Ethiopia and Mozambique the coefficients for religion are

positive. The urban-rural variable shows city residence correlated with a later age at marriage more consistently than religion but with roughly the same influence. Years of schooling are strongly associated with later age at marriage without exception. Women in polygynous marriages are significantly more likely to have married at younger ages. Age at marriage in these countries will clearly increase in the coming years as education and urban residence increase and polygyny declines.

Number of Children Desired

Among married women, two important determinants of fertility are the desired number of children and contraceptive practice. The number desired is measured here by the number considered ideal⁴ and the intention to cease childbearing. These two measures of reproductive preferences are presented for Muslims and non-Muslims in Table 6. The mean number of children desiredⁱ by Muslim women is higher in every country except in Mali in 2012-13 and Tanzania in 2004 (although the positive association is evident in the multivariate analysis described below). A very similar pattern is evident with the proportion of (married) women who want no more children, which is lower for Muslims except in Guinea and Liberia.

Several multivariate analyses are presented in connection with reproductive preferences in order to determine whether the association with Muslims and non-Muslims can be explained by interrelations with other covariates. In addition to education, urban-rural residence, polygyny and an age control, we include the number of living children, the number of child deaths, wealth, exposure to radio and television, and two indices intended to assess attitudes toward the status of women (who makes various decisions in the home and attitude toward husbands' beating of wives, both coded with a positive direction indicating the more egalitarian position).

The multiple regression results in Table 7 indicate that even with all of the controls, Muslims are still associated with a desire for larger families in all 18 countries with this positive relationship maintained at statistically significant levels for 15 countries. Countries with the highest predictive values for the number of children desired from the Muslim – non-Muslim distinction are Ethiopia, Ghana, Kenya and Nigeria. Other variables that relate directly with the number of children desired in this multivariate analysis include the actual number of children which would be expected, later ages at marriage, and the number of child deaths. The latter association strengthens the implication that a reduction in child mortality will ultimately lead to a decline in fertility. Education and wealth are also universally connected with a desire for fewer children (with the exception of Chad). Urban residence is for the most part related to wanting fewer children although there is less consistency. With few exceptions, polygyny is associated with a desire for more children. Exposure to radio and television shows some evidence of relating to a desire for fewer children although there are numerous exceptions. And finally, the measures of gender equality also tend to indicate a

⁴ Non-numeric responses such as: "It's up to God" have been assigned a value one standard deviation above the average number desired by those responding with a number.

preference for smaller families. This latter association with the two gender equality measures which is over and above the association with the Muslim – non-Muslim difference is not in accord with another study of four Asian countries that concluded that the general pronatalist attitudes of Muslim women “cannot be accounted for by any general tendency of Muslim women to have less autonomy than non-Muslim women” (Morgan, et al., 2002). A simple comparison of the averages of these two measures for Muslim and non-Muslim women in 16 countries indicates consistently more egalitarian attitudes on the “decision” measure for non-Muslim women but less difference on the “beating” indicator (not shown).

These results are for currently married women most of whom already have children which, of course, can be expected to influence the number desired. A clearer picture can be seen by confining the analysis to young women under 20 years of age. The mean number of children desired by young Muslim women is greater in 14 of the 18 countries averaging 5.1 compared with 4.4 by non-Muslim teenagers. A multiple regression analysis with a reduced number of covariates relevant for younger women is shown in Table 8 and again shows a direct statistically significant effect of being Muslim in most of the countries. Education is strongly inversely related to the number of children desired and viewing television also shows a negative impact. Rural residence generally shows a positive effect.

The other measure of reproductive preferences included in this analysis is the proportion of married women who say they want no more children. In all but two of the countries (Guinea and Liberia), non-Muslim women are more inclined to want to cease childbearing (Table 6).

An additional multiple logistic regression looks at whether women want more or no more children with a control for the number of existing children (Table 9). Also included are the covariates seen before. Significant odds ratios for the Muslim – non-Muslim variable are evident in 15 of the 18 countries showing higher proportions of Muslims wanting more children. The countries with the strongest association are the same as listed above in connection with the desired number of children (plus Cameroon). Other covariates of intention to terminate childbearing besides the obvious connections with age and number of children, are years of schooling, child deaths, and one of the measures of gender equality. These variables indicate that the intention to have no more children increases with education and with a greater participation of women in various decisions in the household.

Contraceptive Practice

In the Muslim world, there is no universal formal opposition to family planning. Two reviews of this subject both concluded that Islam is permissive of family planning (Boonstra, 2001) and that Islam is not a barrier to programs aimed at reducing unplanned pregnancies (Roudi-Fahimi, 2004). This does not imply that local religious leaders are in accord with this view.

In most of the 18 countries, the percentage of married Muslim women currently using a method of contraception is lower than for non-Muslims. Exceptions include Benin, Mali, Tanzania, and Uganda (Table 10). Unmet need for family planning tends to be similar in many countries and does not show a dominant difference by religion. This is probably because Muslims are more likely to desire a birth soon and be classified in the “no demand for contraception” category. The total demand for family planning, the sum of prevalence and unmet need, shows lower proportions of Muslim women in every country except for Mali and Tanzania.

A multivariate analysis of the factors affecting ever use of contraception is shown in Table 11. The “ever use” measure is preferred to current use because of the typically low prevalence in sub-Saharan countries. The odds ratios indicate that being Muslim is associated with lower levels of ever use of contraception controlling for all of the other covariates in all of the countries with the exceptions of Benin, Tanzania and Uganda where there is no difference. Strong associations appear in Cameroon, Chad, Ethiopia, Guinea, Kenya, Malawi and Nigeria. The number of children desired is consistently associated with less contraceptive use. Years of schooling and wealth show consistent positive odds ratios with the use of contraception. Exposure to mass media shows a positive relationship as does one of the gender measures (who makes household decisions). Polygyny is negatively related, but child mortality shows little association.

We also examined the relationship of religion with the length of birth intervals which is related to contraceptive use. Muslim women had shorter birth intervals than non-Muslim women in many of the countries (especially in Cameroon, Ethiopia and Kenya) but in only a few did this connection remain in the multivariate context (not shown).

Child Mortality

Child mortality rates are declining rapidly in sub-Saharan Africa but, as we have seen, it still remains a factor in relation to reproductive behavior. Since the present study focuses mainly on covariations with religion we have examined the possibility of child mortality differences between Muslims and non-Muslims. The short answer is that in only 7 of the 19 countries are there significant differences, all with higher rates for Muslims. The greatest difference is for Nigeria where among women with at least one live birth, 47 percent of Muslim women report having had at least one child death compared with 34 percent of non-Muslims. Other countries with significantly higher mortality of children among Muslims are Cameroon, Ethiopia, Ghana, Guinea, Liberia and Sierra Leone. In most countries, but not including Nigeria, Cameroon and Ghana, the imposition of controls for the number of births, education and the use of contraception erases the religious difference in child mortality.

Summary and Conclusions

This study has focused on an analysis of the association between religion and fertility in sub-Saharan Africa. It is based on data from the Demographic and Health Surveys which

include only a single question on religion (identification with a particular religion). Since there is little difference in fertility between Catholics and Protestants but typically higher fertility for Muslims, the analysis concentrates on Muslim – non-Muslim differences in 18 countries in the region.

There are strong differences in nuptiality. Higher proportions of Muslims are currently married with consistently earlier ages at marriage. Polygyny is more common among Muslims. Reproductive preferences, measured by the standard question on ideal number of children and by the proportion of married women who want no more children, are both strongly related to the Muslim – non-Muslim dichotomy. This association with higher fertility indicators is subjected to multivariate analyses which include existing number of children, rural-urban residence, education, wealth, child mortality, polygyny, mass media exposure and two measures of gender equality, but the connections with religion are not eliminated.

An analysis of the association of contraceptive use with the Muslim – non-Muslim difference yields similar results in a multivariate context. Unmet need for family planning shows a mixed picture across countries but the total demand for family planning estimated by the sum of modern contraceptive prevalence and unmet need clearly indicates a greater demand by non-Muslim women.

The persistent association of the Muslim – non-Muslim effect on these reproductive measures with numerous covariates controlled may lie in some aspects of the religion itself or in its local practices. More likely, it may result from other unobserved covariates or from inadequate measurement of those included, such as the status of women. If one considers the declines in Muslim fertility in other countries such as Bangladesh or Indonesia, the conclusions of Gavin Jones (2006) seem appropriate that there is nothing intrinsic to Islam in connection with fertility which would suggest in our study the eventual disappearance of the Muslim effect on fertility in Africa.
